
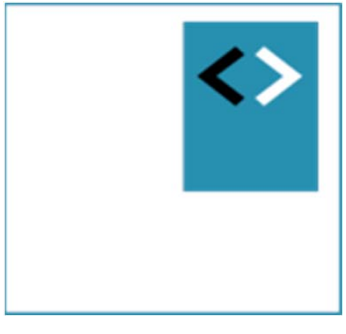
React Fundamentals
Module – working with data

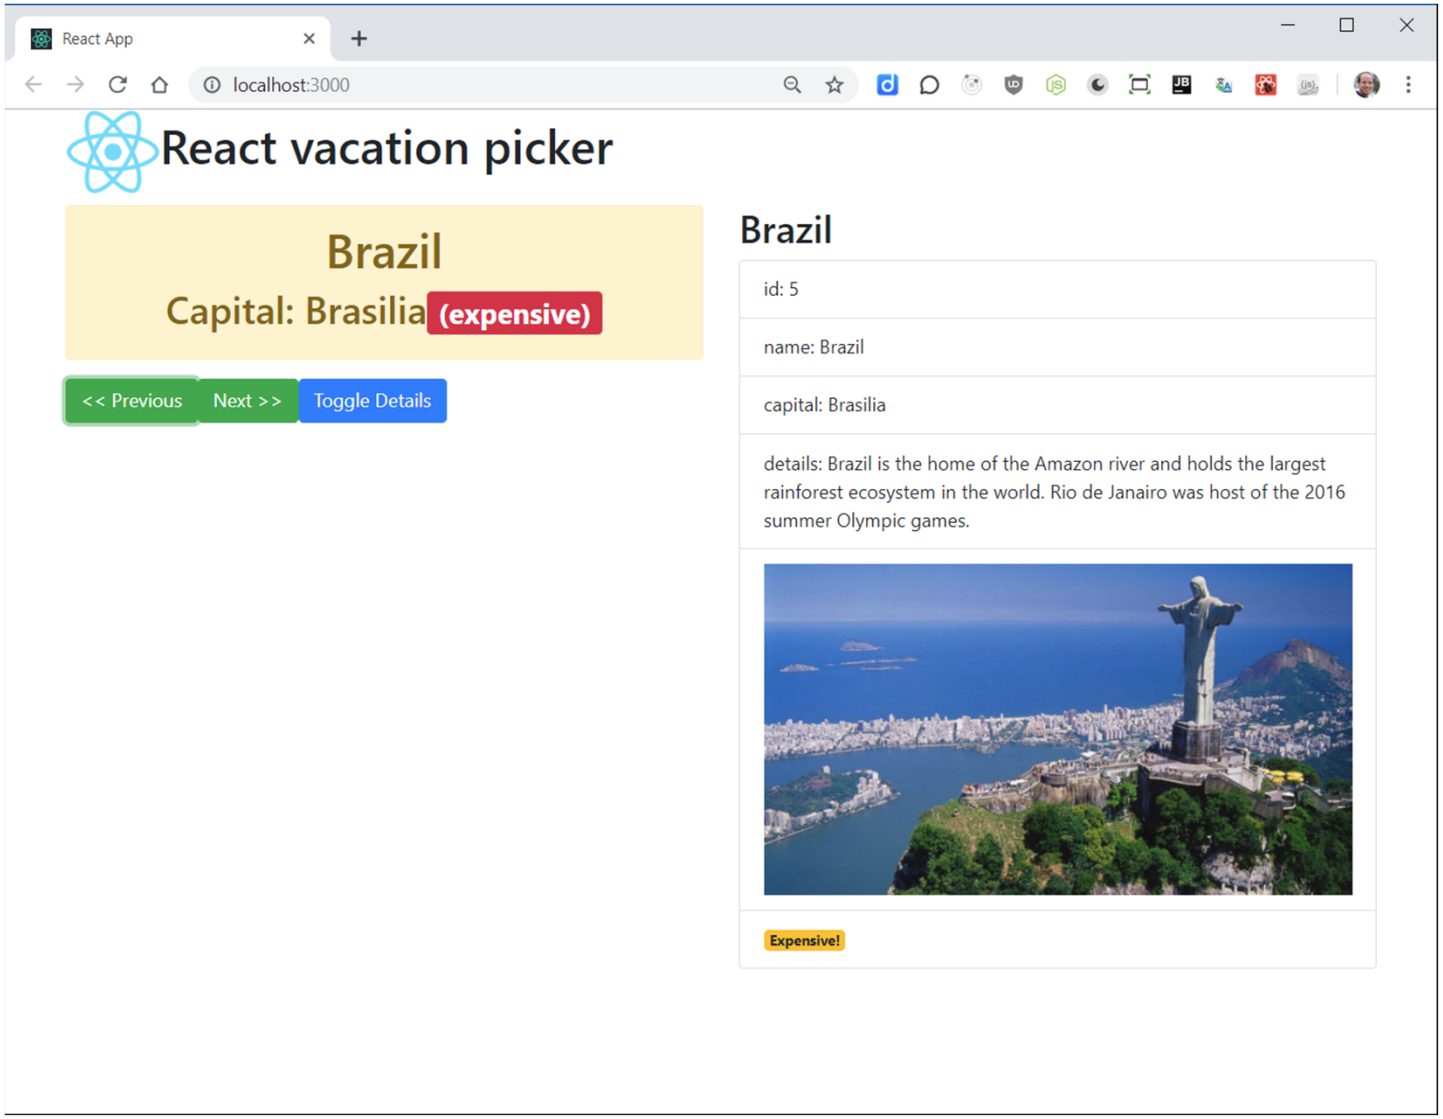


Peter Kassenaar –
info@kassenaar.com

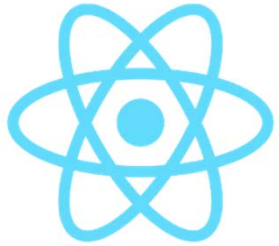
Working with data

Importing local and external data in your app

What are we going to build?



Building an app: VacationPicker



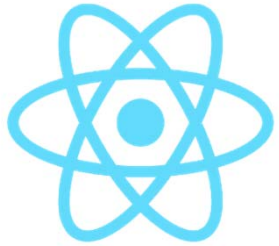
- Requirements:
- Loading external data
  - Comes from `.json/.js` file
  - Later the data will be fetched from a ‘real’ API
- Looping over- and displaying data
- Selecting data – showing details
- Binding images
- Conditionally render pieces of the UI

Creating the data file

```
// ./data/countryData.js - holding an array of country/capital data.
// This of course will come from a real db in the future.
const data = {
   countries: [
      {
         id: 1,
         name: 'USA',
         capital: 'Washington',
         cost: 1250,
         details: 'United States are among the most visited country in the world.',
         img: 'washington.jpg'
      },
      {
         id: 2,
         name: 'Netherlands',
         capital: 'Amsterdam',
         cost: 795,
         details: 'The capital of the Netherlands, Amsterdam, is over 1000 years old.',
         img: 'amsterdam.jpg'
      },
      { …
}
```

Our example: a simple JavaScript object, holding an array with countries and some (fake) data, don't forget to `export` it!

New component(s)



Create a new component, `VacationPicker.js` with the default content

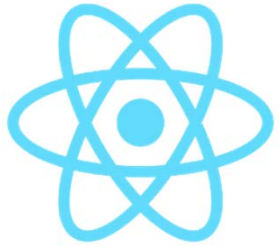
```
// VacationPicker.js
import React, {Component} from 'react';

class VacationPicker extends Component {

    render() {
        return (
            <div>
                <h1>List of Countries…</h1>
            </div>
        );
    }
}

export default VacationPicker
```

Updating <App />



```
// App.js
import React, {Component} from 'react';

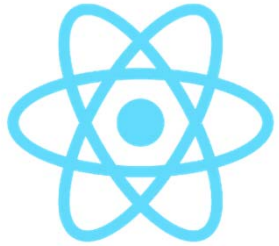
// Child components
import VacationPicker from './VacationPicker/VacationPicker'

// Our parent component - it later holds the state for the child components
class App extends Component {

// Render UI
    render() {
        return (
            <div className="container">
               <h1>React Vacation Picker</h1>
               <VacationPicker/>
            </div>
        )
    };
}

export default App;
```

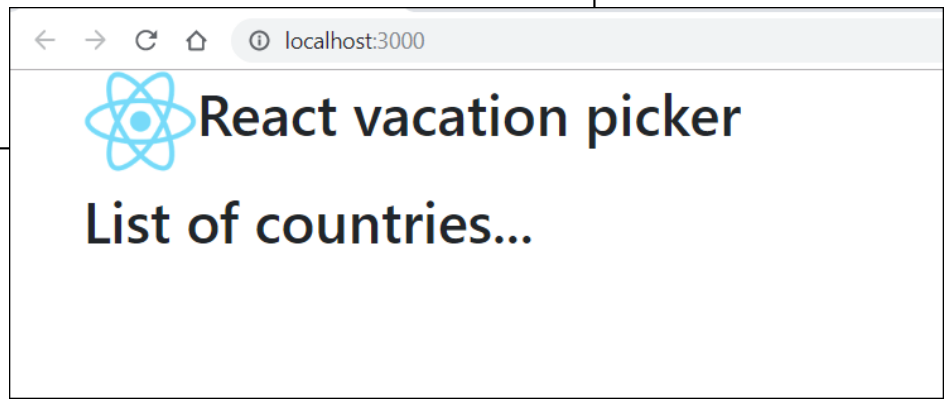
Adding the Logo



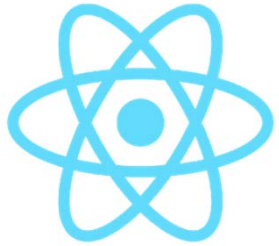
- Static images must be imported before they can be bound in JSX

```
import logo from '../img/logo-react-small.png'
```

```
…
<h1>
    <img src={logo} alt="react logo" width={80}/>
    React vacation picker
</h1>
<VacationPicker/>
```



Importing the data



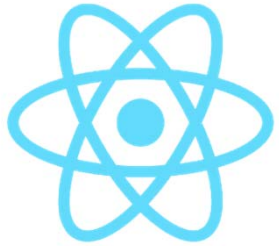
- Use default `import` statement for the `countryData.js` file
- Data is made available as a `prop` on the component

```
// App.js
import countryData from '../data/CountryData';

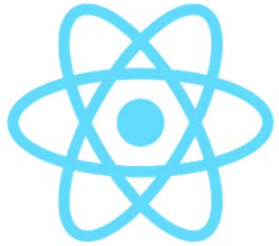
class App extends Component {
    state = {
        countries: countryData.countries,
    };

    render() {
        return (
            <div className="container">
                …
                <VacationPicker countries={this.state.countries}/>
            </div>
        )
    };
}
```

Binding to data

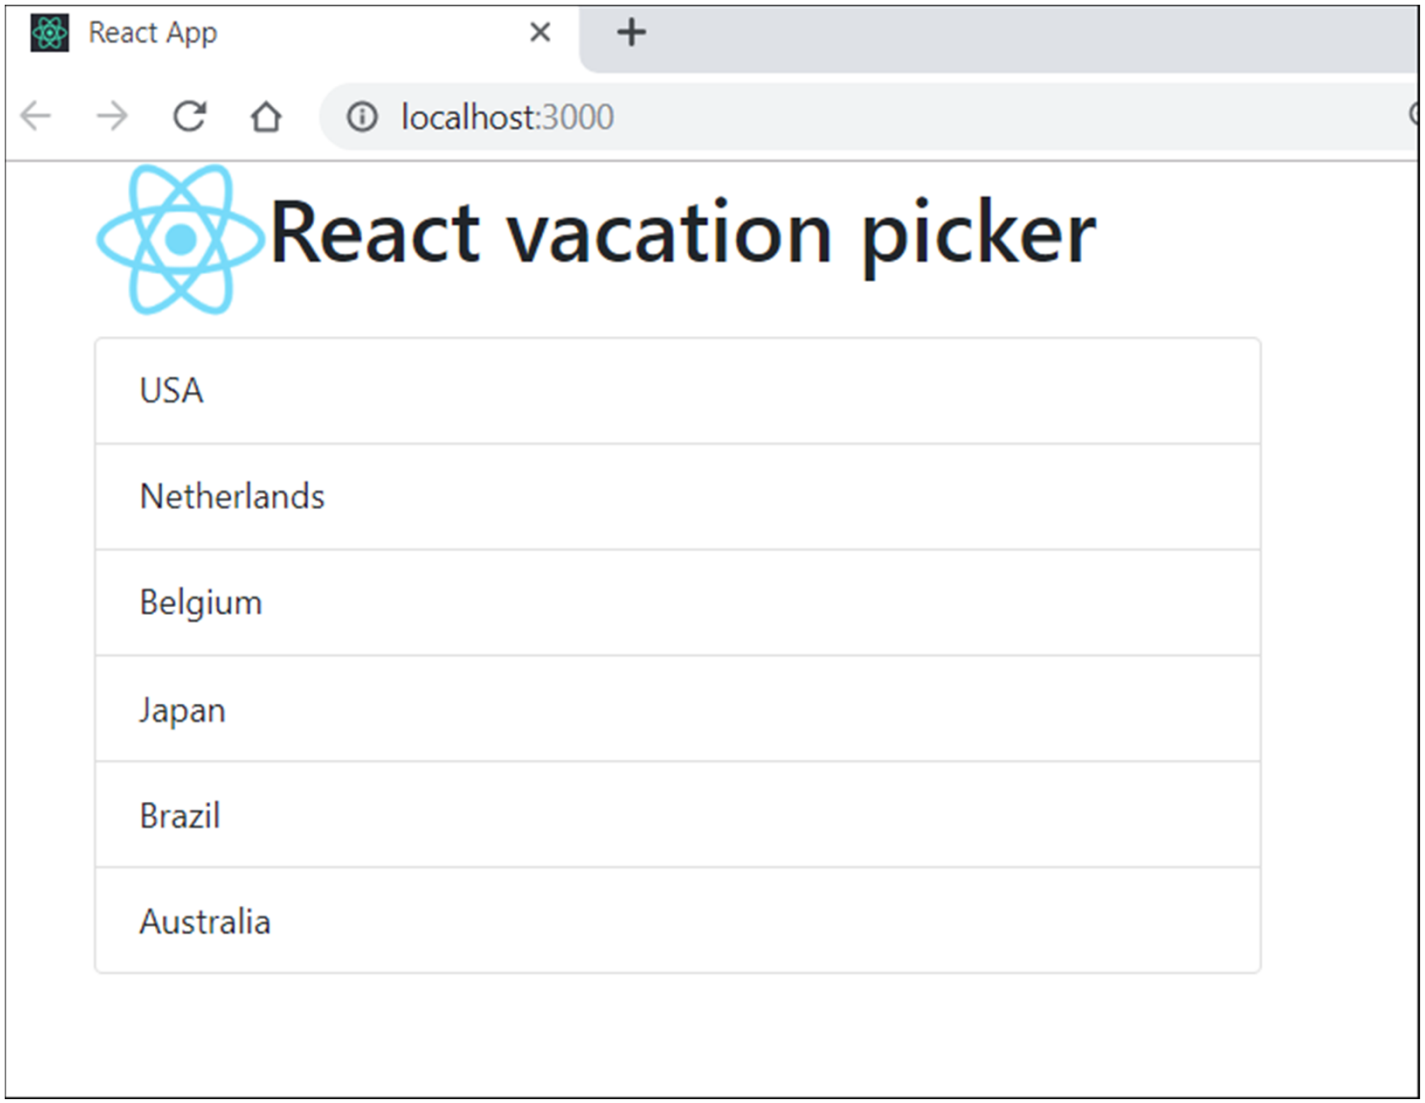


- Use a default JavaScript `.map()` function to render the data.
- Remember, we are looping over a JavaScript object!
- In React, you can put any JavaScript expression inside curly braces in the JSX
  - Like `{this.props.countries.map(…)}`
- Inside the expression your render additional UI



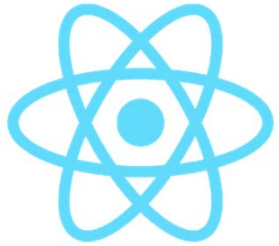
```
// VacationPicker.js
class VacationPicker extends Component {
  ..
    render() {
        return (
            <div>
                <ul className="list-group">
                    {this.props.countries.map(country =>
                        <li className="list-group-item"
                            key={country.id}
                            id={country.id}
                            title={country.details}
                        >
                            {country.name}
                        </li>
                    )}
                </ul>
            </div>
        );
    }
}
```

Result



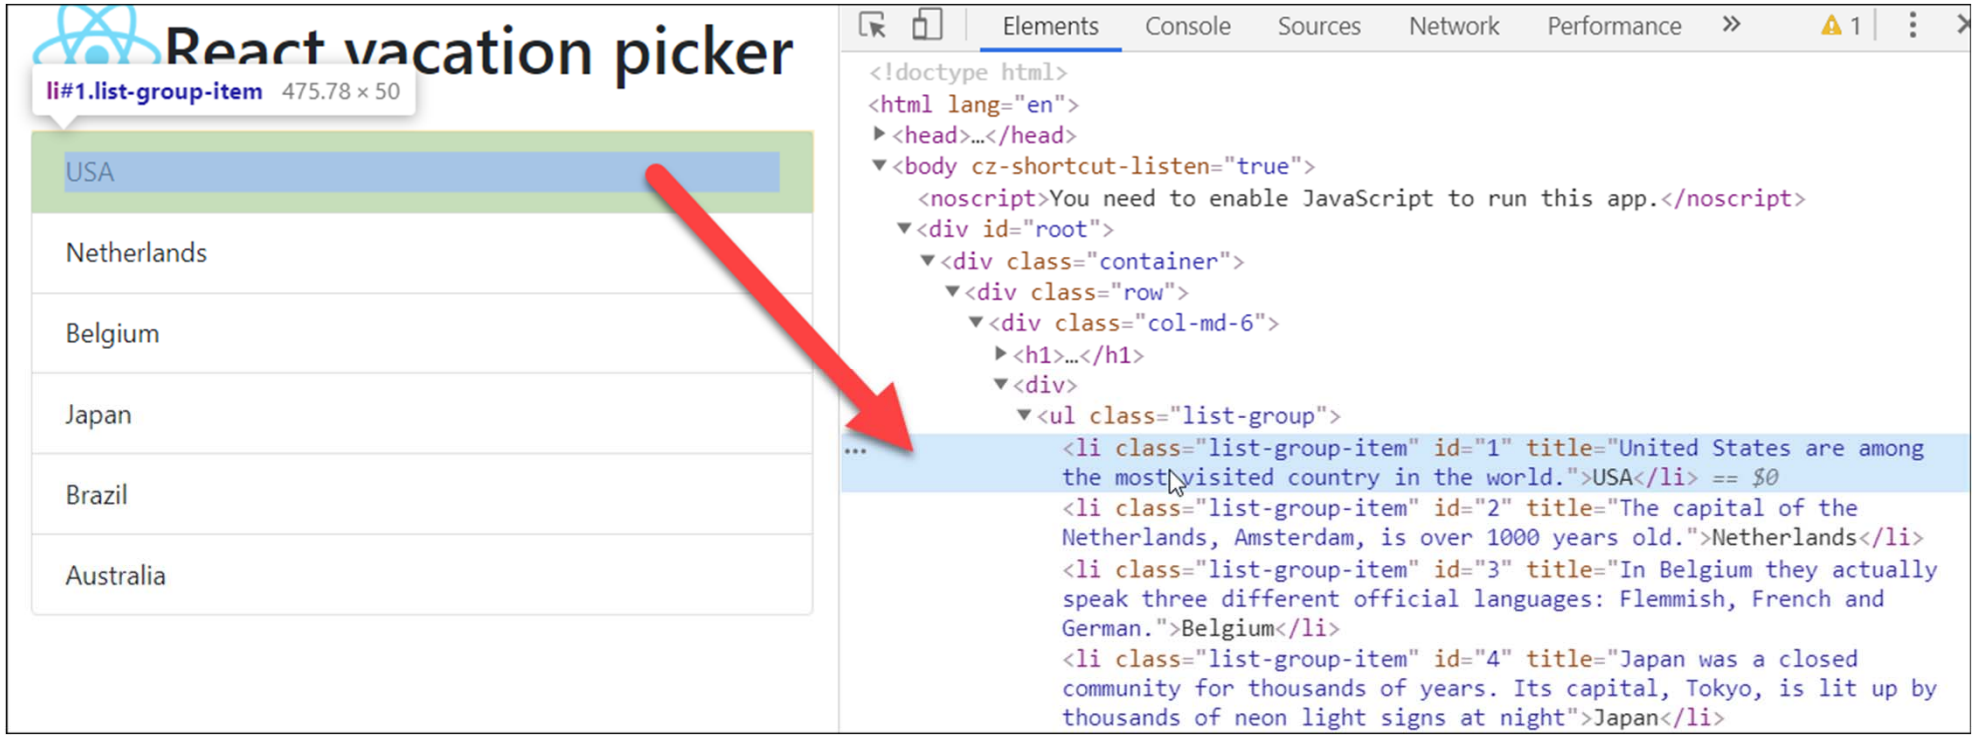
React App
localhost:3000
React vacation picker
USA
Netherlands
Belgium
Japan
Brazil
Australia

Binding to attributes

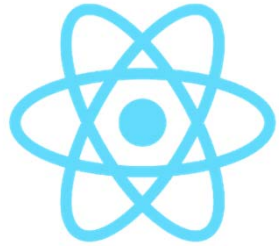


- Note that we are binding data to attributes here
  - `key` - to create a unique React-key for each list item
  - `id` – to create an HTML-`id` for each list item
  - `title` – to create a small popup if one hovers over the item
- In React, you use *single curly braces* to assign attribute values
  - `id={country.id}` - Good
  - `id="country.id"` - Bad
  - `id="{country.id}"` - Bad

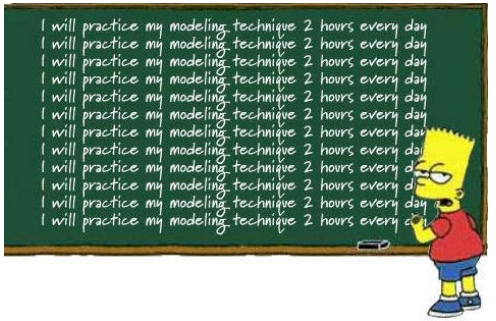
Result in the DOM



Workshop

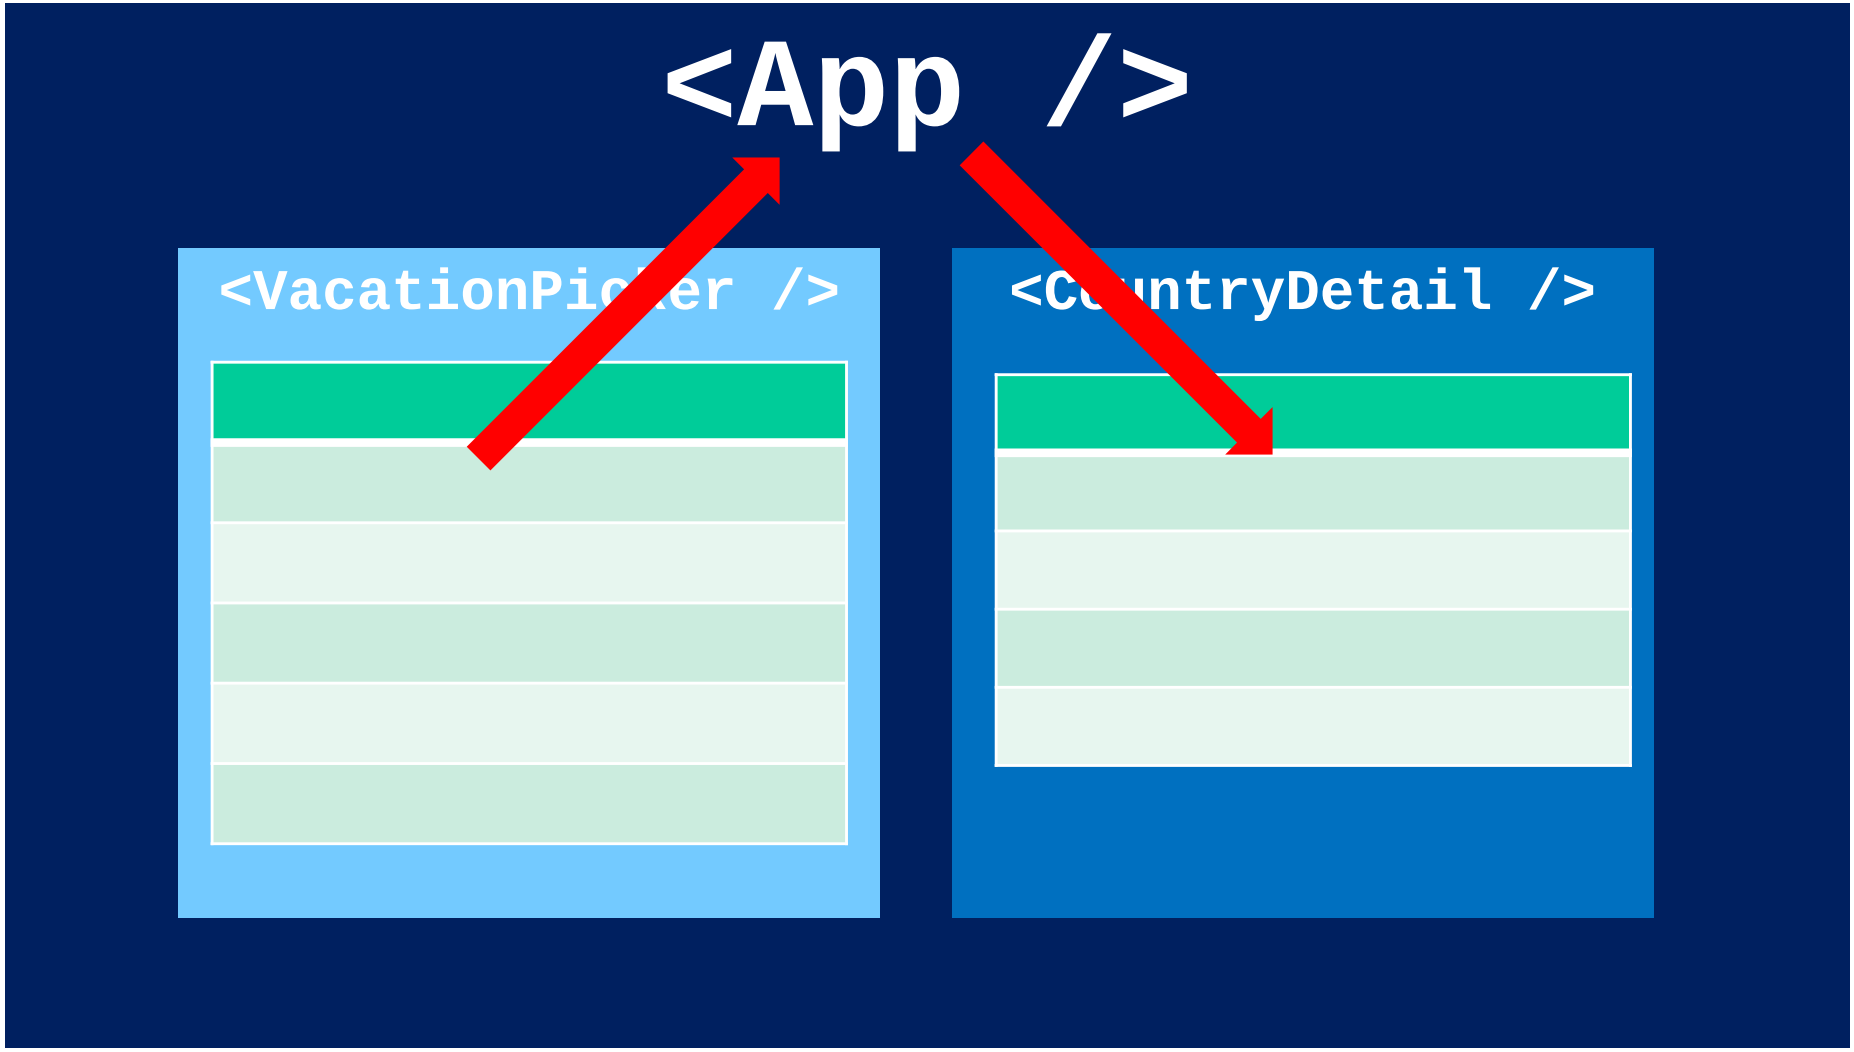


- Add a data file to your application.
  - You can use `countryData.js` as an example, or build your own data file
  - Use for instance `CustomerData.js` as a blueprint and add your own data
- Import the data file to your application
- Show its contents in a new component, or inside `VacationPicker`, using `.map()`
- Create a key binding for your data
- Example: `../200-data-list`



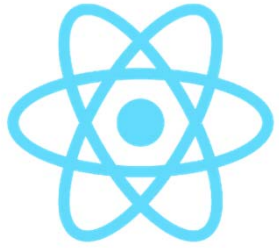
Selecting a specific country

Passing details to a specific component



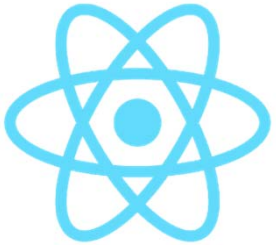
<App />
<VacationPicker />
<CountryDetail />

Selecting a specific country



1. Create a `<CountryDetail />` component
2. Define new state property on `<App />`
    - we call it `currentCountry`
3. Pass state to `<CountryDetail />`
4. Write method to set new `currentCountry` on click
5. Update `<VacationPicker />` to transfer the clicked country up to `<App />`

1. Creating CountryDetail



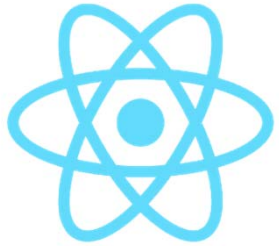
Create a component as usual.

```
// CountryDetail.js - show details of a specific country
import React, {Component} from 'react'

// A pure presentational component
class CountryDetail extends Component {
    render() {
        const country = this.props.country;
        return (
            <div>
                <h2>{country.name}</h2>
                <ul className="list-group">
                    <li className="list-group-item">
                        id: {country.id}
                    </li>
                    …
                </ul>
            </div>
        )
    }
}
export default CountryDetail
```

Render all items from the passed in country

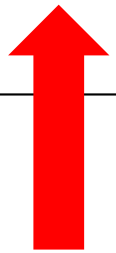
2. Define state for current country



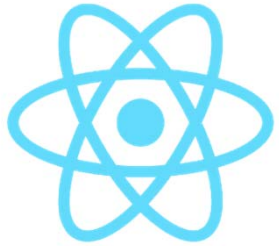
Design decision: the first country in the list is by default the selected country

```
// Our parent component - it holds the state for the child components
class App extends Component {

    state = {
        countries: countryData.countries,
        currentCountry: countryData.countries[0]
    };
}
```



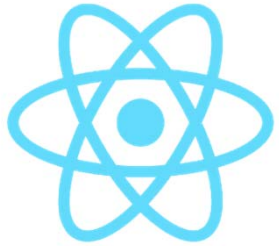
3. Pass the state to <CountryDetail />



Render the component in the UI of App.js like normal

```
<div className="container">
   …
      <div className="col">
         <CountryDetail country={this.state.currentCountry}/>
      </div>
</div>
```

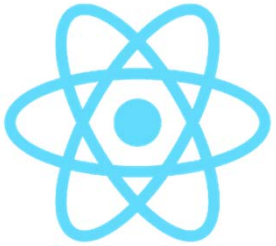
4. Write method to update the state



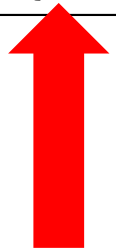
```
selectCountry(country) {
    const newIndex = this.state.countries.indexOf(country);
    this.setState({
        currentCountry: this.state.countries[newIndex]
    })
}
```

`selectCountry()` will be called if a specific country in the list is clicked. So we need to pass this function as a prop

Calling selectCountry()



```
<VacationPicker
    select={(country) => this.selectCountry(country)}
    countries={this.state.countries}/>
```



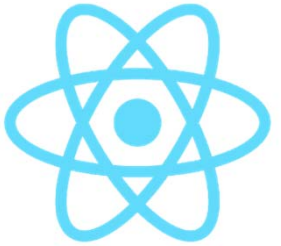
Note: the country that is passed to selectCountry()

is coming from the <VacationPicker />.

So we *need* to define this as a parameter for the

incoming function call

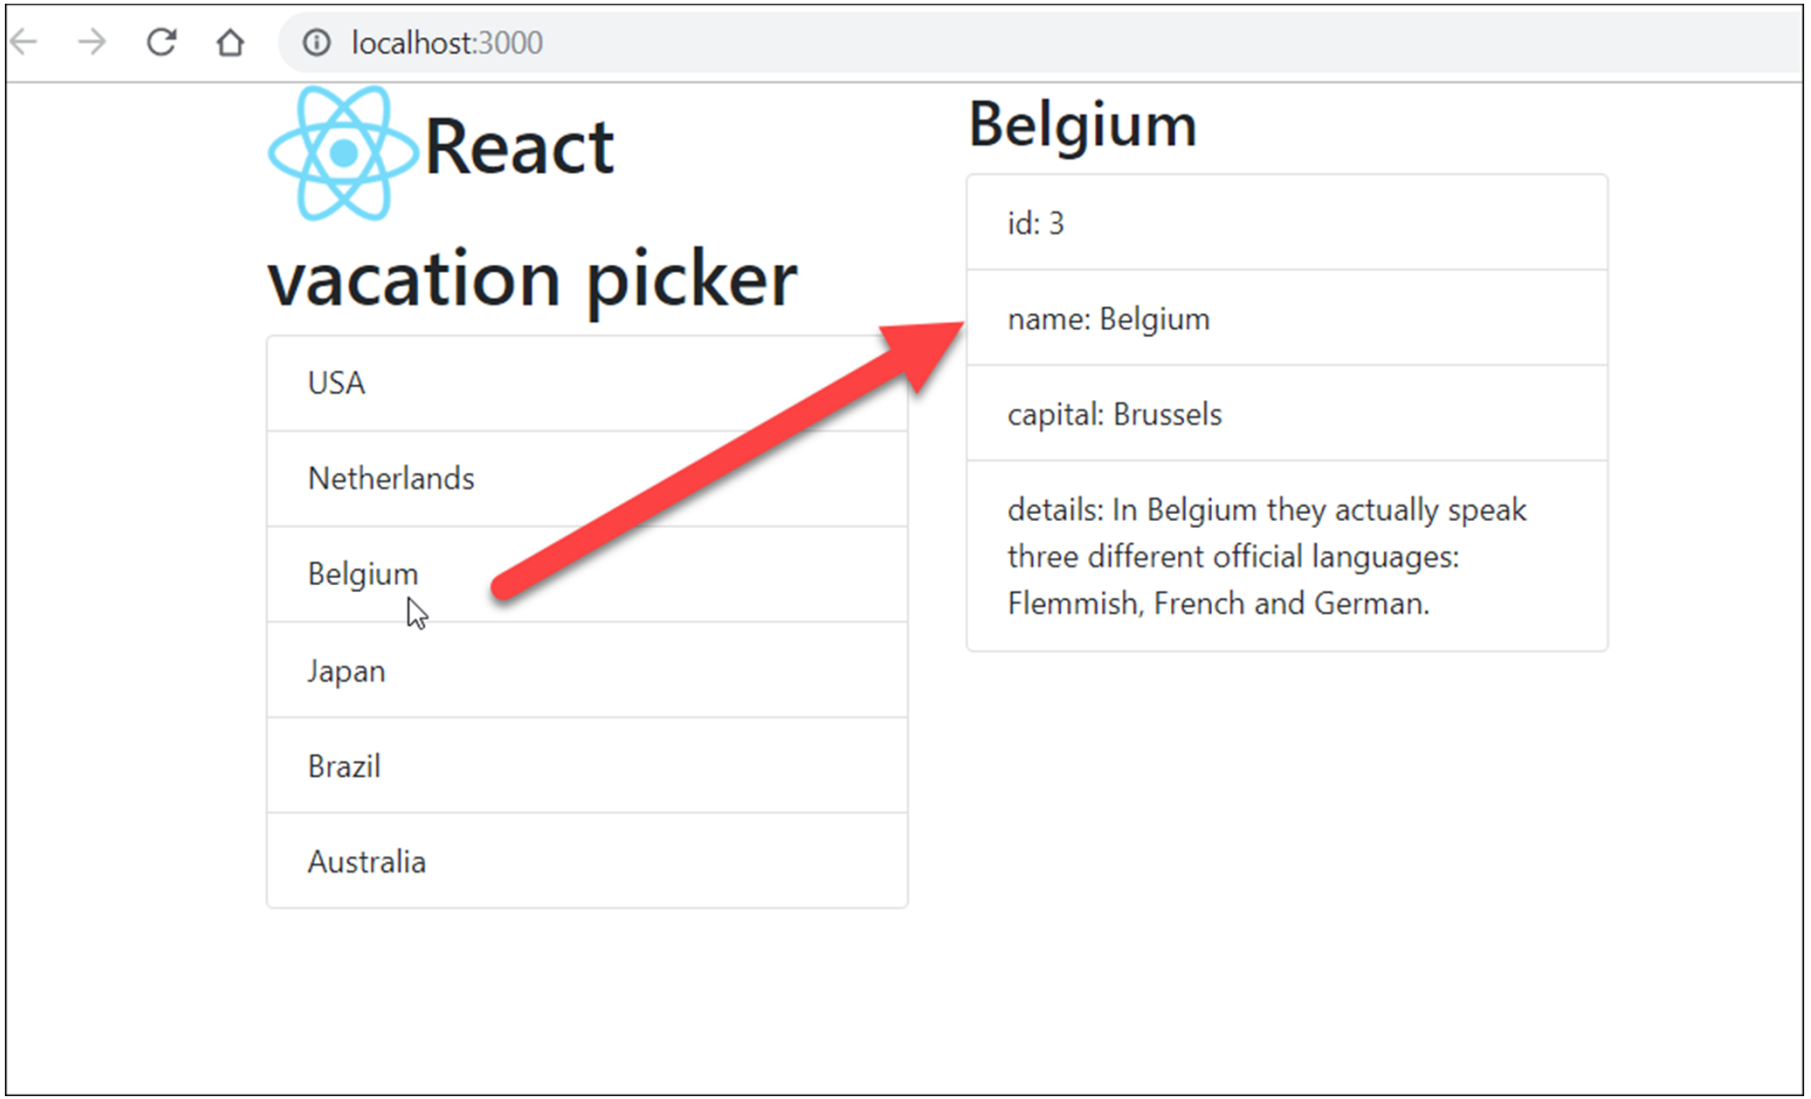
5. Update <VacationPicker />



```
class VacationPicker extends Component {

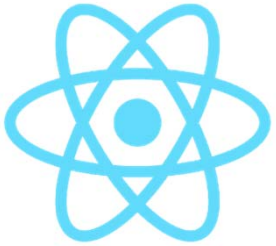
    render() {
        return (
            <div>
                <ul className="list-group">
                    {this.props.countries.map(country =>
                        <li className="list-group-item"
                            …
                            onClick={() => this.props.select(country)}>
                            {country.name}
                        </li>
                    )}
                </ul>
            </div>
        );
    }
}
```

Result

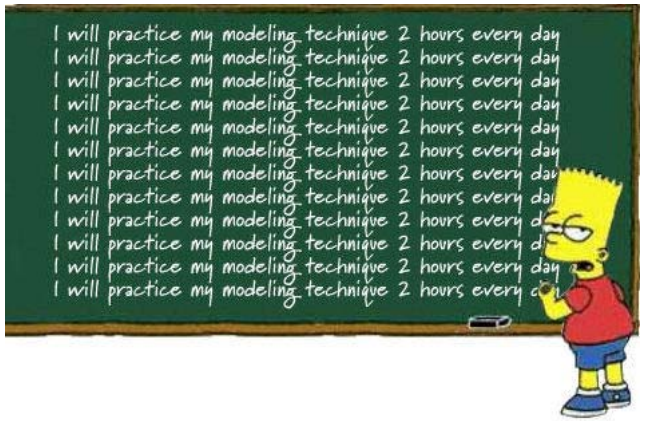


localhost:3000
React
vacation picker
USA
Netherlands
Belgium
Japan
Brazil
Australia
Belgium
id: 3
name: Belgium
capital: Brussels
details: In Belgium they actually speak three different official languages: Flemmish, French and German.

Workshop



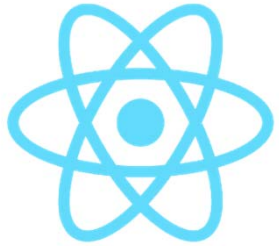
- Create a detail view for your own app.
  - If an element/data is clicked, show details in the UI
  - Remember to pass data to the detail component
- Ready made example: `../210-data-detail`
- You can also work from this example and create a *new* detail component and pass for instance only `country.name` as an exercise



Rendering images

Showing dynamic images in the UI

Static images

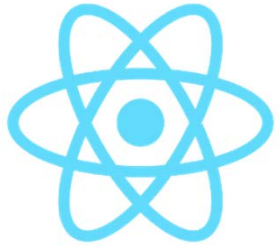


Like the logo: import first, then use as a variable reference

```
import logo from '../img/logo-react.png'
import background from '../img/background.jpg'
```

```
<img src={logo} alt="react logo" width={80}/>
<img src={background} alt="background" />
```

Dynamically binding to images

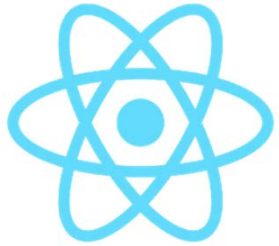


- React can not simply interpolate the name of an external resource and re-use it for binding
  - For instance, the `src` attribute of an image.
- So this is invalid:

```
<img
    className="img-fluid"
    src={'../../img/countries/' + country.img} alt={country.name}/>
```

Invalid!

WebPack to the rescue

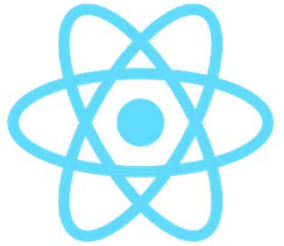


- Because Webpack builds JavaScript strings of everything, it needs to be able to determine the location of the requested file
- Use `require()` that returns a string with the correct location:

```
<img
    className="img-fluid"
    src={require('../../img/countries/' + country.img)} />
```

Correct!

Using ES6 string interpolation

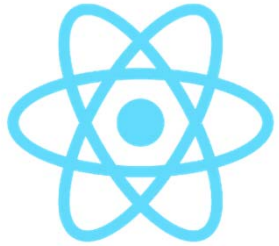


- You can also use ES6 string interpolation, like so:

```
<img
    className="img-fluid"
    src={require(`../../img/countries/${country.img}` )} />
```

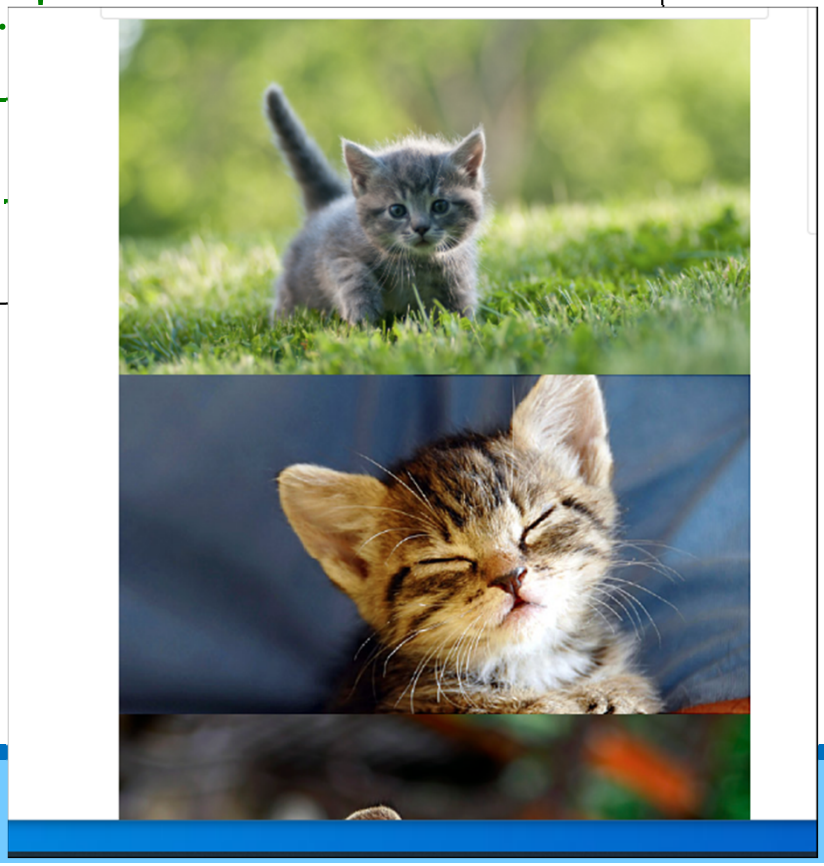
Correct!

Full URL's

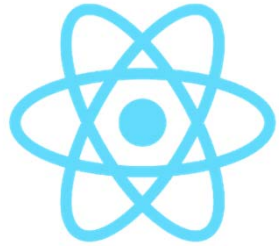


When the image is a fully qualified URL, directly binding inside <img> is correct

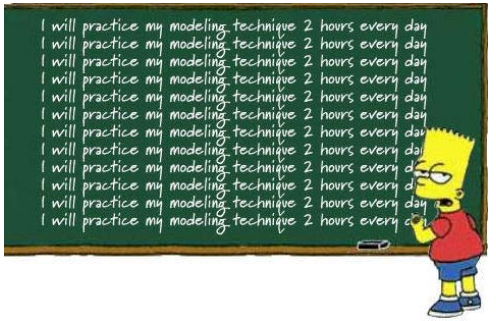
```
cats = [
    'https://www.vets4pets.com/siteassets/.
    'https://img.webmd.com/caring_for_your_
    'https://images.unsplash.com/…',
    'https://imgix.bustle.com/uploads/safe-
];
```



Workshop



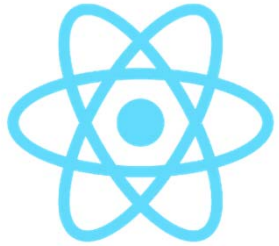
- Own application: add images to your data and render them dynamically in the app
- Ready made example `../220-image-binding`
- Optional: create a new component, holding an array of static images (fully qualified URL)
  - Render them in a loop to the UI
  - (like in the previous slide)



Conditional rendering

Only show some UI if a certain condition is met

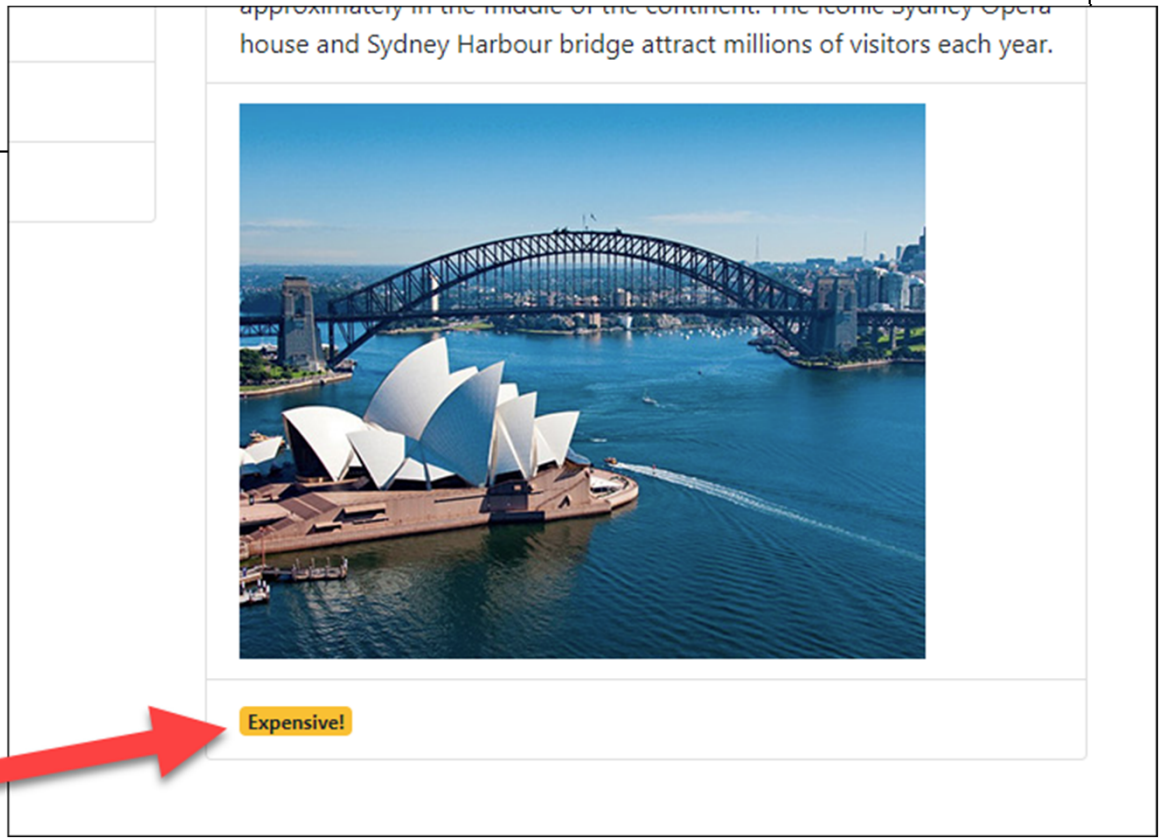
Adding conditions to the UI



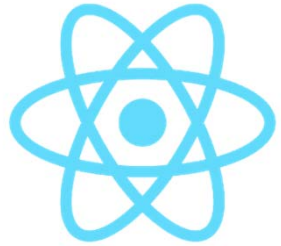
- We want to show a badge if a destination is `expensive`
  - Decision: “a destination is expensive if it costs more than 4000”
- Remember: you can just write JavaScript expressions between `{ … }`
- We’re using a ternary statement `? … :…` here.
- React does *not* have a construct like `v-if`, or `*ngIf`, like Vue and Angular

Writing a conditional statement

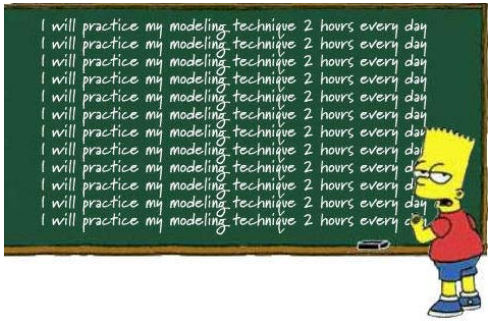
```
{country.cost > 4000 ?
    <li className="list-group-item">
        <span className="badge badge-warning">Expensive!</span>
    </li>
    : ''
}
```



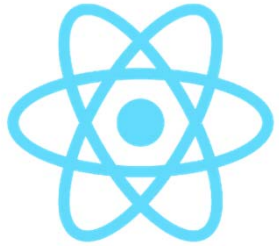
Workshop



- Create an ‘on sale’ label, if a destination is cheaper than 1000
- Show the `expensive` and on `sale` badges directly in the list
- Create a button that shows/hides the country details
- Example `../230-conditional-rendering`
- Optional: create a `favorite` property on the data model.
  - Inside the detail view, users can mark the item as favorite.
  - The status should show in the list/overview
  - Possible solution: `../workshops/30-binding-favorite`
  - But first try it yourself!



Checkpoint



- You can import static data in your application
- You know how to loop over the data using `.map()` and render it in the UI
- You can select data from the master view and pass it to a detail component
- You can render dynamic images using `require(…)`
- You know how to render pieces of the UI dynamically
